Introduction

The last several years have seen substantial investment in the adoption of electronic health records (EHRs) in the US and elsewhere, offering great potential to improve the quality, safety, and cost of healthcare.\textsuperscript{1} EHR adoption is also likely to improve our ability to advance biomedical and healthcare science and research through the re-use of clinical data.\textsuperscript{2-4}

At the same time, there has been substantial US investment in various aspects of clinical and translational research, including comparative effectiveness research (CER) that aims to study populations and clinical outcomes pertinent to real-world clinical practice.\textsuperscript{5} Additional federal investment in research infrastructure includes the Clinical and Translational Research Award (CTSA) program of the US National Institutes of Health, leading many institutions funded by CTSA awards to develop research data warehouses derived from operational EHRs and other systems.\textsuperscript{6,7} Another source of federal investment has come from the Office of the National Coordinator for Health Information Technology (ONC) through its Strategic Health IT Advanced Research Projects (SHARP) Program, with one of the four major funded research areas focusing on re-use of clinical data.\textsuperscript{8}

Our previous paper reviewed some of the successes of efforts to use operational EHR data for research.\textsuperscript{9} One prominent success has come from the Electronic Medical Records and Genomics (eMERGE) Network, which has demonstrated the ability to validate existing research results and generate new findings mainly
in the area of genome-wide association studies (GWAS) that associate specific findings from the EHR (the “phenotype”) with the growing amount of genomic and related data (the “genotype”). Another successful effort has come from analyses derived from the Health Maintenance Organization Research Network’s Virtual Data Warehouse (VDW) Project, where, for example, researchers were able to use data to demonstrate a link between hyperglycemia in pregnancy and childhood obesity. Using similar methods, other researchers have been able to replicate the findings of randomized controlled trials using EHR data and appropriate statistical methods.

As we noted, however, routine clinical data are collected for clinical and billing uses, not research. We described and detailed several caveats for the use of such data for CER, including inaccuracy, incompleteness, transformation in ways that undermine their meaning, inaccessibility for research, unknown provenance, insufficient granularity, and incompatibility with research protocols. Informed by these caveats, and motivated by the potential benefits of re-using operational clinical and administrative data for research, quality measurement and improvement, and other analytical purposes, we believe that there have been significant informatics advances in support of such reuse. In this paper, we adopt the critical appraisal approach of evidence-based medicine (EBM) to the problem, discuss some of the informatics challenges to the use of operational clinical data for CER, and then develop an informatics roadmap for moving forward.

**Recommendations for Using EHR Data for CER**
The following sections outline nine major recommendations for advancing the use of operational EHR for CER (see Figure 1). Table 1 provides a summary and description of each recommendation, which correspond with the sections and facets in the rest of the paper.

**Table 1 – Summary of recommendations for advancing the use of operational EHR data for CER.**

<table>
<thead>
<tr>
<th>Recommendation</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Apply an Evidence-Based Approach</td>
<td>Ask an answerable question, find the best EHR data (“evidence”), appraise the data, apply data to the question</td>
</tr>
<tr>
<td>Evaluate and Manage Data</td>
<td>Assess availability, completeness, quality (validity), and transformability of data</td>
</tr>
<tr>
<td>Create Tools for Data Management</td>
<td>Create software (especially pipelines) for data aggregation, validation and transformation</td>

**Apply an Evidence-Based Approach**

The EBM process offers many analogies for that can guide the use of operational clinical data for CER and other forms of research. Some may consider EBM to be antagonistic to EHR data re-use, as EBM gives the most value to evidence from controlled experiments, especially randomized controlled trials (RCTs), while viewing the use of real-world observational data as a lower quality form of evidence, due to its being incomplete, incorrect, and/or inconsistent. In reality, observational data analysis holds a role toward CER (or any type of clinical research) that is different from and complementary to that of traditional clinical trials. RCTs provide information on efficacy in well-defined populations under tightly regulated circumstances. Observational studies, by their nature, provide a more real-world view, cover broader populations than can be analyzed in a clinical trial setting, and can explore the associations with and effects of different levels of exposure to the intervention being studied. Therefore, both types of studies are necessary to understand how and why an intervention is working compared with expectations.

In contrast to clinical trials data, EHR data are voluminous and much more reflective of the real clinical world. In addition, performing RCTs on all clinical questions of interest would be prohibitively expensive. But we can look to the process of EBM to guide us in how to best consider EHR data as part of our body of evidence. EBM uses a principled approach to find and apply the best available information to make clinical decisions. In particular, EBM uses four steps that we can apply analogously to research use of EHR data, whether in single institutions...
or across multiple institutions and settings, analogous to the use of systematic reviews and meta-analysis.\textsuperscript{19}

1. Ask an answerable question – In applying EBM, the first step of asking an answerable question may be the most important. For example, knowing to ask whether a test or treatment is efficacious is not enough. Rather, we need to know at a minimum the effectiveness of the intervention relative to some alternative approach in a particular patient population or setting. This same approach is obviously necessary for using operational EHR data for clinical research. In selecting EHR data for use in a study, the researcher should adopt the established population, intervention, comparison, outcomes, timing, and setting (PICOTS) framework for formulating the research question.\textsuperscript{20}

2. Find the best evidence – For the second step, the principle from EBM is very much the same, even if the techniques of obtaining evidence are very different. The "evidence" in this case is the data in EHRs and other systems that, as noted previously, may be incomplete, incorrect, and inconsistent. We therefore need to determine if we have the proper data and, if so, whether they can be applied to answer our question.

3. Critically appraise the evidence – In the third step, just as with EBM, the evidence must be critically appraised. Can we trust the inferences and conclusions from the data? Are there confounding variables in those data? Have the appropriate methods been used? These may be critical with EHR data where assignment of cause and effect could be difficult, if not impossible. The solution likely comes back to asking the right question, i.e., one for which we can have confidence that we have found the correct answer.

4. Apply it to the patient situation – Lastly, we need to ask, can the evidence be applied in our setting? Just as some RCTs answer questions in patient populations very different from those of the clinician making decisions, we must ascertain if the results obtained from this approach can be applied to a specific clinical context.

As EBM recognizes that the single studies are limited to reflecting a single setting and often with small sample sizes, the techniques of systematic review and meta-analysis have been developed to aggregate results from multiple studies and, where possible, aggregate their data in meta-analysis. The equivalent of this approach for clinical data is combining clinical data from multiple settings or institutions.

\textit{Evaluate and Manage EHR Data for CER}
Any research study, whether CER or not, require the highest quality data available for observing the object of that study. For data coming from an operational EHR, this means we need to determine whether the data required are available, complete, and valid.

To illustrate the need for these types of data evaluation and management apparatus and tools, figure 1 shows a prototypical workflow consisting of the major steps needed to assess such factors for each datum in a study that uses EHR data. This process is inclusive of recommendations about data management, including evaluating data, tools for data management, metrics for data assessment, and methods for comparative validation.

Once the researcher defines the question, he or she must then identify the EHR data elements corresponding to the desired data and determine whether they are actually available. For each desired datum, he or she must next assess if that element is complete, i.e., available for all individuals whose data will be used in the study. Of course, determination of data completeness and data quality are challenging.\textsuperscript{21,22}

Figure 1 – Assessing data from operational sources for clinical research.
In addition to determining whether data are available and complete, the researcher must also ascertain whether the data are valid. As was seen in the caveats above, we know there are many reasons why data are not valid. A review by Weiskopf and Weng identified methods that have been used in the past to assess the validity.
of data. These included comparison to a gold standard, agreement of data elements among sources, comparison of data distribution across sources, validity checks, review of data capture logs, and element presence in multiple sources. If the data are not valid, then the researcher must determine if it is possible to transform them. There are a number of ways that data can be transformed, such as combining them with other data, e.g., linking claims and EHR data or adding data from other sources. Of course, such transformation requires further validity-checking.

If individual data are not available, complete, or transformable, then the researcher must either continue the study with noted limitations, or he or she must find alternative and/or surrogate sources of data. The researcher must also carefully consider the usefulness and relevance of each data element against a testable hypothesis and an analytic model or analytic plan in order to be efficient with the time of those maintaining and performing operations on the data. Often the scope of technical and methodological skills and tools required to address the preceding information needs is beyond the capabilities of an individual researcher, necessitating the engagement of a broader, multi-disciplinary team of investigators, informaticians, and research or technical support staff. Building upon this requirement and informed by the findings and caveats introduced previously, we consider several critical facets of our recommendations, with the objective of ultimately motivating a CER-relevant informatics research and development agenda aligned with them. An illustration of the interrelationships between our proposed recommendations, their constituent facets, and the data-analytic workflow introduced in Figure 1 is then provided by the elements in Figure 2. We now describe these facets.
Figure 2 – Relationships between core datum assessment operations and the facets of informatics research and development needed to support and enable comparative effectiveness research.

Facet 1: Tools and methods capable of supporting the aggregation, transformation, and validation of heterogeneous data sets

Investigators who carry out certain types of research, such as CER but also including health services research, epidemiology, pharmacogenomics, and genome-wide association studies, all need to aggregate information obtained from different health systems and their data sources. In all of these cases, investigators must also aim to verify the accuracy of information obtained from each source and use the appropriate tools to transform and optimize the data for research use. In order to satisfy such information needs in a scalable and contextually
appropriate manner, CER investigators must be provided with access to highly-
usable, configurable, and shareable tools and methods that can be used to build,
instrument, and apply data-analytic pipelines targeting the preceding
requirements. Such pipelines would ideally be composed of multiple “plug ins”
or modules that are made available for community-wide re-use via public libraries
or equivalent means.

CER researchers using EHR and other operational data must also apply methods
to ensure their completeness and quality. Emerging methods for data
completeness include explicit and predictive analysis of data in the EHR.\textsuperscript{21}
Likewise, methods for data quality assessment include such techniques as checks
for adherence to common data models across sites and comparing actual versus
expected observations within sites.\textsuperscript{22, 26} CER researchers must also work with
clinicians, health care organizations, and others to improve the data that informs
their “downstream” research.

It is also possible to gain insight into potential approaches to specific data
aggregation and quality assurance best practices based on analogous efforts that
have been undertaken in the context of methods used to evaluate the quality and
reproducibility of clinical laboratory results. A variety of tests can be carried out
to characterize internal consistency of results at each site. Results obtained by
laboratories are typically compared; for example, laboratories analyze specimens
produced by an accrediting body such as the College of American Pathologists
(CAP), which then in turn generates reports comparing the performance of
participating laboratories. A comparable approach to testing EHR data could be
developed to ascertain a clinical organization’s ability to produce “research-
grade” data.

Facet 2 – Tools and methods that can enable the comparative validation and
analysis of multi-site data collections

Comparisons between clinical sites are complicated by the fact that patient
populations naturally differ between health systems. However, statistical
properties associated with relationships between diagnostic entities, laboratory
values and medication orders can be evaluated for each site and then compared
from site to site, possibly applying normalization or other transformations of the
data where appropriate. The key here is likely to lie in examining inter-
relationships between co-morbidities with given patient demographics; one would
for instance expect characteristic collections of co-morbidities related to each
broad class of diseases. Thus we must develop and use a compendium of
reference information models (RIMs), verification/validation algorithms, and
reference data sets (e.g., for use as comparative “gold standards”) so that CER investigators can draw upon and rigorously apply a well-known, validated, and reproducible “tool box” of comparative analysis methods. For example, a rich set of “sanity check” characterizations can and should be carried out to assess internal consistency of each institution’s clinical data characterizations. For instance, one can expect characteristic constellations of diagnostic codes, laboratory test values and medication orders for a patient classified as having diabetes mellitus (DM) with renal, ophthalmic or neurological manifestations; e.g., a patient classified as having DM with renal complications would be expected to have abnormal estimated glomerular filtration rate (eGFR) and/or proteinuria.

Facet 3 – Tools and methods for data transformation and/or synthesis in support of CER

As noted previously, CER researchers require validated point-by-point comparative data among the study populations. The use of EHR data presents unique challenges for obtaining sufficient data of the particular comparators whether the study compares, for example, different medications, medical devices, or types of surgical vs. non-surgical interventions. Many EHR systems are not designed to collect accurate and complete data sets that are sufficiently robust for such comparisons

Other unique challenges and needs in CER are the lack of nationally adopted data-related research methodologies that can be utilized in person-centered comparative outcomes studies and pragmatic studies that reflect real-world settings. EHR data that are collected, archived, and made accessible must be standardized across EHR vendors and users with ongoing procedures (as described in the previous section) to ensure consistency of results within sites and comparability across sites. For example, patient-reported outcomes, patient problem lists, and functional outcome measures are now collected using different tools, and may not be uniformly or completely collected in EHRs. In addition, there are differences in services provided, data entered by health care entities, and information provided by patients that contribute to the inconsistency of completeness and accuracy of EHR data for CER.

The above challenges need to be addressed to advance CER through the development of widely applicable methodological and technical solutions. One approach is the creation, maintenance, and dissemination of collections of platform-independent: 1) data capture instruments; 2) algorithms for the inference or synthesis of complex and potentially temporally dependent phenotypes from primary data; and 3) knowledge management technologies and best practices.
Such tools could support improved understanding of data provenance in EHRs and other systems such that researchers have a sufficient understanding of the sources and potential biases surrounding the data for a given research study.

**Develop a Methodology Knowledge Base**

In addition to devising methods and tools for improved data reconciliation and integration as introduced in the three preceding facets, solutions to the challenges that face those attempting to re-use data for research purposes require an informatics roadmap. Such an informatics roadmap must include resources to aid CER researchers in applying complex methods arising from the use of operational data. At the simplest level, a resource that lays out the concerns raised in this article is needed to which CER researchers can refer. This may include for example, a table relating data elements and types and transformations recommended or not. Such a resource – a methodology knowledge base – would need to be updated as novel issues are raised, as novel solutions are offered, and as instructive examples are shared. The next level would be a more interactive resource that supplies this knowledge in a more active mode than a passive knowledge base. CER researchers, especially novice ones, employing EHR data could benefit from the integration of methodological decision support into their research environment. This should also include new research methodologies as well as new ways to measure and encourage research-related activities during routine practice. 29, 30, 31

Another informatics challenge and opportunity is making the efficient recording of high-quality and standardized data easier for clinicians. As noted above, clinical documentation is not usually a priority for busy clinicians. 32, 33 Research has shown clinicians already spend a substantial amount of time (20-103 minutes per day) entering data related to patient care. 34 Where possible, clinicians must be aided by the easy incorporation of other sources of reliable data. 35 We also must “bake in” data standards so that their use by clinicians and others in the health system is seamless. 36 Better adherence to standards upfront will be make data interoperability easier downstream, especially in its use for CER.

Whereas traditional observational studies usually enlist a human being to enter data into a research database, manual curation in large-scale EHR-based studies is not practical. Therefore, an even more detailed description of the exact data sources and methods to encode the data into research variables is needed to allow future researchers to repeat a study more reliably, to compare studies, and to better identify potential biases in the results. For example, when there are multiple database queries for the same intended search, e.g., “all patients with diabetes,”
this may be searched as all patients “with a diabetes-related billing code,” “with a
 diabetes-related problem listed on their last problem list,” “with an order for
 insulin, “with an elevated hemoglobin A1C level,” or any number of other
 methods. The performance characteristics (e.g., sensitivity and positive predictive
 value) of these queries should be ascertained or at least alternative methods
 should be compared and reported.

**Standardize Metadata Reporting**

Likewise, the readers and consumers of research using these data require
reporting methods that go beyond stating the source of the data or a cursory
explanation of how they were transformed. To this end, much more detailed
methodology of data sources, provenance, and manipulation must be provided in
sufficient detail to provide an understanding and the limitations of such use. This
will likely require a reporting standard comparable to the Consolidated Standards
of Reporting Trials (CONSORT) and STrengthening the Reporting of
Observational studies in Epidemiology (STROBE) tools. The STROBE
checklist, for example, stipulates that all outcomes, exposures, predictors,
potential confounders, and effect modifiers be clearly defined, giving diagnostic
criteria (if applicable) and that for each variable of interest, sources of data and
details of methods of assessment (measurement) be given, describing
comparability of assessment methods if there is more than one group being
studied.

Creating a common format for reporting such details would be beneficial, as
researchers would be encouraged to provide complete information that make
comparison of studies easier. The format can be seen as way of presenting an
explicit description of a study’s data assumptions. Multicenter observational
studies may require separate descriptions for each institution if the algorithm used
to generate the study variables differs among institutions. The description may
require not just the researcher’s procedures, but also a description of relevant
aspects of how the EHR is used in the institution. For example, if only a subset of
clinicians use order entry, then using orders as a source for coding the use of a
medication could bias the results.

Studies using EHR data must also embrace the diversity of disease definitions in
ways that set different expectations for presentation of results than for clinical
trials. Results of clinical trials provide a single point estimate and a confidence
interval. Observational studies, on the other hand, should present multiple results
under different assumptions. Sensitivity analyses should be the norm in reports of
these types of analyses. Readers should see how results compare under different
assumptions regarding disease definitions. If results are robust to assumptions, the findings are strengthened. If results differ, then the trends in the difference related to the characteristics of the underlying cohorts should be clinically plausible. Adhering to a “clinical trial” standard of making an a priori decision about cohort definition, and presenting findings based on that one analysis, can be unintentionally misleading (or purposefully misleading if the investigators did test different cohorts and reported on only one result that supports their hypotheses).

**Engage Informatics Expertise**

Of course, as the sections above illustrate, there are numerous informatics issues that must be addressed to enable the successful re-use of clinical data for CER. To that end, another key recommendation must be for data-based research projects to include experts in biomedical informatics, a field closely related to but distinct from computer science, IT, and biomedicine. Just as the inclusion of those with particular methodological expertise in key research activities (e.g., biostatisticians, subject matter experts, etc.), the inclusion of informatics experts can help address the validity of findings generated during CER studies that rely on the re-use of clinical data often collected initially for different and varied purposes and deriving from disparate systems.

**Generate an Informatics Roadmap for CER**

Achieving the goals of the recommendations as outlined will require an informatics research agenda. There has been very little study, for example, of how the EHR (or really any medical record) works and what biases the health care process creates in its data. This is an especially challenging area because whereas completeness and accuracy are somewhat apparent and measurable, bias is insidious. The data may look about right, but due to influences such as the health care process, the effects on the recorded data can influence the outcome. We must study workflows, develop and evaluate user interfaces that allow the entry of high-quality data in time-efficient ways, and characterize the limitations of all data to better assess how they can be improved. Such research is not simply a part of the methodology of a clinical study but a research endeavor in its own right.

While there are many caveats related to the reuse of operational clinical data, there are also tremendous opportunities. Some successes have already been achieved, and with attention to the techniques proposed in this paper, we believe that additional ones will likely be forthcoming.
